autism • oxidative stress • genotype • glutathione • methionine

ABSTRACT

Autism is a behaviorally defined neurodevelopmental disorder usually diagnosed in early childhood that is characterized by impairment in reciprocal communication and speech, repetitive behaviors, and social withdrawal. Although both genetic and environmental factors are thought to be involved, none have been reproducibly identified. The metabolic phenotype of an individual reflects the influence of endogenous and exogenous factors on genotype. As such, it provides a window through which the interactive impact of genes and environment may be viewed and relevant susceptibility factors identified. Although abnormal methionine metabolism has been associated with other neurologic disorders, these pathways and related polymorphisms have not been evaluated in autistic children. Plasma levels of metabolites in methionine transmethylation and transsulfuration pathways were measured in 80 autistic and 73 control children. In
addition, common polymorphic variants known to modulate these metabolic pathways were evaluated in 360 autistic children and 205 controls. The metabolic results indicated that plasma methionine and the ratio of S-adenosylmethionine (SAM) to S-adenosylhomocysteine (SAH), an indicator of methylation capacity, were significantly decreased in the autistic children relative to age-matched controls. In addition, plasma levels of cysteine, glutathione, and the ratio of reduced to oxidized glutathione, an indication of antioxidant capacity and redox homeostasis, were significantly decreased.

Differences in allele frequency and/or significant gene-gene interactions were found for relevant genes encoding the reduced folate carrier (RFC 80G > A), transcobalamin II (TCN2 776G > C), catechol-O-methyltransferase (COMT 472G > A), methylenetetrahydrofolate reductase (MTHFR 677C > T and 1295A > C), and glutathione-S-transferase (GST M1). We propose that an increased vulnerability to oxidative stress (endogenous or environmental) may contribute to the development and clinical manifestations of autism. © 2006 Wiley-Liss, Inc.

ARTICLE TEXT

INTRODUCTION

The Centers for Disease Control and the American Academy of Pediatrics have recently released an “Autism Alarm” indicating that the current prevalence of autism is ~1 in 166 children in the US (CDC, 2005). The ~tenfold increase in autism diagnosis in the last two decades has generated major public health concern. Nonetheless, research progress has been slow and the biologic basis of this complex disorder remains unknown. Prevailing evidence supports the involvement of both genetic and environmental factors that interact to negatively affect prenatal and postnatal neurologic development [Folstein and Rosen-Shellsey, 2001; Keller and Persico, 2003]. A strong genetic component is widely accepted based on the high concordance among monozygotic twins and the tenfold increase in risk among siblings of affected children relative to the general population [Bailey et al., 1995]. Because monozygotic twin concordance is less than 100%, environmental and epigenetic factors have also been implicated and are thought to be necessary to expose the genetic liability. However, despite intense research effort, no single gene or specific environmental factor has been reproducibly identified [Muhle et al., 2004]. It has been estimated that at least 10-15% of the “susceptibility alleles” contribute to the phenotype and that different combinations of mutant alleles may be involved in different individuals. An interacting environmental trigger further complicates the search for susceptibility genes since many unaffected individuals are likely to carry the same genetic risk factors.

The diagnosis of autism is based solely on behavioral criteria that define deficits in social interaction, impairment in verbal and non-verbal receptive/expressive speech, and hyper-focused repetitive behaviors [Lord et al., 2000]. The pathophysiology of autism primarily affects three major systems: neurologic, immunologic, and gastrointestinal [Hornig and Lipkin, 2001; Horvath and Perman, 2002; Krause et al., 2002; Bauman and Kemper, 2003; White, 2003]. An interesting but poorly understood etiologic clue is the fact that four boys are affected for every girl. Further compounding the complexity, autistic behavior encompasses a heterogeneous and variable spectrum of clinical symptoms [Eigsti and Shephiro, 2003; Tager-Flusberg and Joseph, 2003]. Currently, there is no biochemical test for the presence of autism to support the behavioral diagnosis.

Research into the metabolic basis for autism has been relatively underutilized compared to broad scale genomic and proteomic approaches. An integrated metabolic profile reflects the interaction of genetic, epigenetic, environmental, and endogenous factors that perturb the pathway of interest. In addition, the evaluation of an entire metabolic pathway, as opposed to isolated single gene products, provides greater mechanistic insights into disease pathology and can identify new options for targeted intervention strategies. We have used a targeted approach to “metabolomics” focusing on the dynamics of a single metabolic pathway involving methionine transmethylation and transsulfuration that has been implicated in the pathogenesis of numerous other neurologic disorders [Schuiz et al., 2000; Pogribna et al., 2001; Serra et al., 2001; Miller, 2003; Munifewerff et al., 2003].

In a recent case-control study, we measured fasting levels of plasma methionine transmethylation and transsulfuration metabolites in 20 autistic and 33 control children [James et al., 2004]. The metabolic profile of children diagnosed with autistic disorder with regressive onset was found to be severely abnormal. The autistic children were found to have significant decreases in methionine levels and in the ratio of plasma S-adenosylmethionine (SAM) to S-adenosylhomocysteine (SAM/SAH ratio), an index of methylation capacity. Total glutathione levels (GSH, the major intracellular antioxidant) were decreased and oxidized glutathione disulfide (GSSG) was increased, resulting in a ~threefold reduction in the redox ratio of reduced (active) GSH to oxidized (inactive) glutathione (GSH/GSSG). Cysteine, the rate-limiting amino acid for glutathione synthesis, was significantly decreased relative to the control children suggesting that GSH synthesis was insufficient to maintain redox homeostasis. The present study was undertaken to confirm and extend these observations in a larger cohort of children and to identify potential polymorphisms in candidate genes known to affect the dynamics of these pathways.
A diagram of methionine transmethylation and transsulfuration pathways is presented in Figure 1. The methionine cycle (transmethylation) involves the regeneration of methionine from homocysteine via the B12-dependent transfer of a methyl group from 5-methyltetrahydrofolate (5-CH₃THF) via the methionine synthase (MS) reaction [Finkelstein, [1999]].

Methionine is then activated to SAM, the methyl donor for multiple cellular methyltransferase reactions and the methylation of essential molecules such as DNA, RNA, proteins, phospholipids, creatine, and neurotransmitters [Mato et al., [2002]]. The transfer of the methyl group from SAM results in the demethylated product SAH. The reversible hydrolysis of SAH to homocysteine and adenosine by the SAH hydrolase (SAHH) reaction completes the methionine cycle. Homocysteine can then be either remethylated to methionine or irreversibly removed from the methionine cycle by cystathionine beta synthase (CBS). This is a one-way reaction that permanently removes homocysteine from the methionine cycle and initiates the transsulfuration pathway for the synthesis of cysteine and glutathione as indicated in Figure 1 [Finkelstein, [1998]]:

![Figure 1. An overview of the pathways involved in folate-dependent methionine transmethylation and transsulfuration. Methyltetrahydrofolate (MTHFR) catalyzes the synthesis of 5-methyltetrahydrofolate (5-CH₃THF) from 5,10-methylenetetrahydrofolate (5,10-CH₂H₄F). The methyl group from 5-CH₃THF is transferred to homocysteine to regenerate methionine via the folate/B12-dependent methionine synthase (MS) reaction. Methionine synthase reductase (MSR) maintains the B12 cofactor in a reduced state for optimal MS activity. Methionine is then activated to S-adenosylmethionine (SAM), the major methyl donor for multiple cellular methyltransferase (MTase) reactions. After methyl group transfer, SAM is converted to SAH which is further metabolized to homocysteine and adenosine by a reversible reaction catalyzed by SAH hydrolase (SAHH). Homocysteine may be permanently removed from the methionine cycle by irreversible conversion to cystathionine by B6-dependent cystathionine beta synthase (CBS) which initiates the transsulfuration pathway. Cystathionine is subsequently converted to cysteine, the rate limiting amino acid for the synthesis of the tripeptide, glutathione (Glu-Cys-Gly). Reduced active glutathione (GSH) is in dynamic equilibrium with the oxidized disulfide GSSG form of glutathione. Reduced folates are transported from the plasma into the cell by the reduced folate carrier (RFC). Transport of folate into the intestinal mucosa is mediated by glutamate carboxypeptidase II (GCPII). Vitamin B12 is transported into the cell bound to the B12 transport protein transcobalamin II (TCII). [Normal View: 16K | Magnified View: 36K]]

Subtle alterations in gene expression due to multiple polymorphisms and environmental factors that interact to affect the same metabolic pathway can induce chronic metabolic imbalance and alter nutritional requirements [Gueant et al., [2003]; Liewers et al., [2003]; Bailey and Gregory, [2000]]. Using the abnormal metabolic phenotype in autistic children as a guide for the selection of functional candidate genes, we evaluated common SNPs in genes encoding methyltetrahydrofolate (MTHFR 677C > T, MTHFR 1298A > C), methionine synthase reductase (MTRR 66A > G), transcobalamin II (TCN2 776C > G), catechol-O-methyltransferase (COMT 472G > A), glutathione-S-transferase (GST M1 null, GST T1 null), reduced folate carrier (RFC 80A > G), glutamate-carboxypeptidase (GCPII 1561C > T). These are among several high frequency low penetrance polymorphisms that have been previously shown to modulate metabolite levels in the methionine transmethylation and transsulfuration pathways [James et al., [1999]; Stern et al., [2003]; Beagle et al., [2005]; Castel-Dunwoody et al., [2005]].

**SUBJECTS AND METHODS**

**Participants**

Probands were referral patients recruited from the autism clinics of participating physicians in New York (SMB, KB, MB, PC), and Florida (JUB). The diagnosis of autistic spectrum disorder was made by independent specialists not associated with the study using criteria defined by the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV), the Autism Diagnostic Observation Schedule (ADOS), or the Childhood Autism Rating Scales (CARS). Patients with childhood disintegrative disorder or rare genetic diseases associated with symptoms of autism (e.g., fragile X, Rett syndrome, tuberculous sclerosis) were excluded from participation. Patient level of functioning ranged from moderate mental retardation to high functioning based on physician evaluation. The autistic children were between 3 and 14 years of age (mean 7.3 ± 3.2), were 97% Caucasian, 89% male, and 11% female. Control children for the metabolic study were healthy Caucasians with no history of chronic disease, autism, or other neurologic disorder who had participated as controls for similar metabolic studies of children with Down syndrome [Pogribina et al., [2001]] and cystic fibrosis [Innis et al., [2003]]. The mean age and SD of the control children was 10.8 ± 4.1 years. Case and control children taking high-dose vitamin
supplements or medications known to affect methionine metabolism were excluded from the metabolic study. The protocol was approved by the Institutional Review Board of the University of Arkansas for Medical Sciences and parental written informed consent was obtained.

Metabolic Analysis

Fasting blood samples from 80 autistic and 73 unrelated control children were collected into EDTA-Vacutainer tubes and immediately chilled on ice before centrifuging at 4,000g for 10 min at 4°C. Plasma aliquots were transferred into cryostat tubes and stored at -80°C until extraction and HPLC quantification. All samples were analyzed within 1 month of receipt. For determination of total homocysteine, methionine, total glutathione, cysteine, and cysteine, 10 µl samples of plasma were added to 200 µl plasma to reduce all sulfhydryl bonds and incubated at 40°C in a shaker for 30 min. To precipitate proteins, 250 µl ice-cold 10% meta-phosphoric acid was added, mixed well, and the sample was incubated for an additional 30 min on ice. After centrifugation at 18,000g for 15 min at 4°C, the supernatant was filtered through a 0.2 µm nylon membrane filter (FGC Scientific, Frederic, MD) and a 20 µl aliquot was injected into the HPLC system.

For determination of SAM, SAH, adenosine, and free reduced glutathione and oxidized disulfide glutathione (GSSG), 100 µl of 10% meta-phosphoric acid was added to 200 µl plasma to precipitate protein; the solution was mixed well and incubated on ice for 30 min. After centrifugation for 15 min at 18,000g at 4°C, supernatants were passed through a 0.2 µm nylon membrane filter and 20 µl was injected into the HPLC system.

The separation of metabolites was performed using HPLC with a Shimadzu solvent delivery system (ESA model 580) and a reverse phase C18 column (5 µm; 4.6 x 150 mm, MCM, Inc., Tokyo, Japan) obtained from ESA, Inc. (Chesford, MA). A 20 µl aliquot of plasma extract was directly injected onto the column using Beckman Autosampler (model 507E). All plasma metabolites were quantified using a model 5200A Coulouche II and CoulArray electrochemical detection systems (ESA, Inc.) equipped with a dual analytical cell (model 5010), a 4-channel analytical cell (model 6210) and a guard cell (model 5020). The concentrations of plasma metabolites were calculated from peak areas and standard calibration curves using HPLC software.

Genetic Analysis

For the genetic analysis, blood samples were obtained from an additional 280 autistic children who did not qualify for the metabolic study because they were not fasting or were taking vitamin supplements (total case n = 360). An additional 132 unaffected controls (total control n = 205) consisted of participants in an ongoing study of congenital heart defect risk described previously [Hobbs et al., 2005]. Genomic DNA was extracted using Puregene DNA Purification Kit (Gentra Systems, Inc., Minneapolis, MN). Genotyping was performed with allele-specific fluorescent primer-probe sets supplied by ABI Assays by Design (Applied Biosystems, Foster City, CA) and primer and probe sequences are listed in Table I. PCR reactions were carried out with ABI PRISM 7700 and 7900 Sequence Detection Systems under the following thermal cycling conditions: one cycle at 95°C for 10 min (Taq activation), followed by 40 cycles of 92°C for 15 sec (denature) and 60°C for 1 min (anneal/extend). The reaction components were as follows: 900 nM of each primer, 200 nM each probe, 25 mM each dNTP, 1 M Tris-HCL (pH 8.4), 1 M MgCl₂, 300 mM KCl, ROX reference dye, 100% glycerol, 0.5 U Taq DNA polymerase (Invitrogen, Carlsbad, CA), and 50 ng genomic DNA. The PCR primers for GST M1 and T1 are listed in Table I; PCR conditions for GST M1 and GST T1 have been previously reported [Ye and Parry, 2002]. The PCR products were visualized on a 2.5% agarose gel with Reliant FastLane Gel System (Cambrex, Rockland, ME). The presence or absence of 215 bp band or 480 bp band reflected the GST M1 and GST T1 positive or null genotypes, respectively.

COMT G472A (Val158Met)
Allelic discrimination was accomplished by fluorogenic probes with either a 6FAM or VIC reporter dye attached to the 5’ end of the oligonucleotide that is cleaved by the 5’ nuclease activity of Taq DNA polymerase.

Statistical Analysis
Metabolic data are presented as the means ± SD. The data were prospectively collected and analyzed using SigmaStat software. Statistical differences between case and control children were determined using the Student’s t-test with significance set at 0.05. For the genotype analysis, odds ratios and 95% confidence intervals were calculated using unconditional logistic regression models and tested using chi-square analysis. Cases and controls were tested for Hardy-Weinberg equilibrium using the exact test implemented in STATA GENHW command [Cleves, 1999]. Gene-gene interactions were tested by including appropriate pair-wise indicator variables into unconditional logistic regression models.

RESULTS

Metabolic Study
Fasting levels of plasma metabolites in the transmethylation and transsulfuration pathways among 73 control and 80 autistic children are presented in Table II. Within the methionine cycle, levels of methionine, SAM, and the SAM/SAH ratio were significantly decreased in the autistic children, whereas the levels of SAH, and adenosine were significantly elevated. The transsulfuration pathway metabolites, cysteine, total glutathione (free-reduced plus protein-bound), and free reduced glutathione were significantly decreased while cystathionine and the oxidized disulfide form of glutathione, GSSG, were significantly increased. The ratios of total glutathione and free reduced glutathione to oxidized GSSG (redox ratios) were also significantly reduced.

\textsuperscript{a} Means ± SD.

Because the severity of clinical symptoms often varies widely between autistic children, the proportion of autistic children with more clinically severe metabolite alterations was also determined. Within the transmethylation pathway, a subset of 50\% of autistic children had methionine levels less than 20 \textmu{mol/L} (mean: 16.6 ± 1.8), 20\% of the children had SAM levels <75 \textmu{mol/L} (mean: 65 ± 8), and 19\% had SAH levels >28 nmol/L (mean: 38.6 ± 5.6). A subset of 25\% of children had adenosine levels >0.30 \textmu{mol/L} (mean: 0.43 ± 0.15). Within the transsulfuration pathway, 65\% of the children had cysteine levels <170 \textmu{mol/L} (mean 155 ± 14) and 51\% had total glutathione levels <5.0 \textmu{mol/L} (mean 4.2 ± 0.5). Free reduced GSH <1.5 \textmu{mol/L} was present in 68\% of the children (mean: 1.15 ± 0.2), whereas oxidized GSSG was above 0.35 \textmu{mol/L} in 49\% (mean: 0.53 ± 0.16). This subset analysis indicates that there are significant numbers of autistic children whose metabolic profiles are severely abnormal.

\textbf{Genotyping}

All genotype distributions were in Hardy-Weinberg equilibrium and all control allele frequencies were consistent with previous reports [Palmati, et al., 1999; Geisler and Olshan, 2001; Skibola, et al., 2004; Gueant-Rodriguez, et al., 2005]. In the univariate analysis, there were no significant differences in allele frequency or genotype distributions at the \textit{P} < 0.05 level between autistic cases and unaffected controls for \textit{MTHFR} 677C > T, \textit{MTHFR} 1298A > C, \textit{GST T1} null, \textit{GCP 156C} > T, or \textit{MTRR 86A} > G. Significant increases in odds ratios, allele frequencies and genotype distributions among autistic children were found for \textit{RFC-1 80A} > G, \textit{TCN2 776C} > G, and \textit{COMT 472G} > A genes. An increase in the frequencies of \textit{MTHFR 677CT} and \textit{GST M1} null genotypes among autistic cases achieved borderline significance. A decrease in the \textit{MTRR} homozygous GG genotype and G allele frequency also achieved borderline significance among cases. The odds ratios and 95\% confidence intervals for these variant alleles are presented in Table III.

The significant gene-gene interactions are presented in Table IV. Three genotype combinations were found to have odds ratios greater than the individual genotypes alone. Among the autistic children, 9.8% inherited the combined homozygous GG genotypes for COMT and TCN2 (four mutant alleles) compared to 2.5% of control children, raising the odds ratio to 7.0. Homozygous or heterozygous combinations of RFC G allele and the MTHFR 677 T allele (3-4 mutant alleles) also resulted in significant increases in susceptibility to autism: GA/CT, OR 3.2; GA/TT, OR 4.4; and GG/CT, OR 3.1. There was also a significant interaction between the RFC-1 heterozygous GA and homozygous GG alleles and the GST M1 null genotype (3-4 mutant alleles) with odds ratios of 3.78 and 2.87, respectively. An increase in the frequency of compound heterozygous MTHFR 677CT/1298AC reached borderline significance among the autistic children with an OR of 1.78 and also showed an interaction with the RFC 80 G allele.
DISCUSSION

Autism is recognized to have a complex etiology involving both genetic and environmental factors [Keller and Persico, [2003], Muhle et al., [2004]]. The apparent requirement for an environmental trigger plus the genetic and clinical heterogeneity within autism spectrum disorders greatly complicates the search for candidate genes. The endophenotype represents a reproducible expression of the disease that lies between genes and clinical symptoms and may provide insights into susceptibility alleles [Gottesman and Gould, [2003]]. For example, an endophenotype may be a biochemical, neurologic, hormonal, or immunologic biomarker associated with the disease state. Thus, the abnormal metabolic profile we have discovered in autistic children is an endophenotype that may reflect subtle changes in gene products that regulate flux through methionine transmethylation and transsulfuration pathways. Even small variations in gene expression and enzyme activity, if expressed chronically, could have a significant impact on downstream metabolic dynamics. The correlation between the severity and specificity of autistic symptoms and severity and the specificity of metabolite imbalance is of clinical interest and these studies are currently underway.

The significant decrease in total and free plasma glutathione as well as the GSH/GSSG redox ratio in the autistic children is of particular concern. Glutathione is a tripeptide of cysteine, glycine, and glutamate that is synthesized in every cell of the body. The essential intracellular reducing environment is maintained by the high ratio of reduced glutathione (GSH) to the oxidized disulfide (GSSG) form of glutathione [Schaffer and Buettner, [2001]]. The GSH/GSSG redox equilibrium regulates a pleiotropic range of functions that include nitrogen and oxygen free radical scavenger [Dickinson et al., [2003]], protein redox status and enzyme activity [Klatt and Lamas, [2000]], cell membrane integrity and signal transduction [Dickinson and Forman, [2002]], transcription factor binding and gene expression [Derflancke and Gaeckins, [2002]], phase II detoxification [Pastore et al., [2003]], and apoptosis [Hall, [1999]]. Under normal physiological conditions, glutathione reductase enzyme activity is sufficient to maintain the high GSH/GSSG redox ratio. However, excessive intracellular oxidative stress that exceeds the capacity of GSSG reductase will result in GSSG export to the plasma in attempt to regain intracellular redox homeostasis. Thus, an increase in plasma GSSG is a strong indicator of intracellular oxidative stress. Further, GSSG export represents a net loss of glutathione to the cell and increases the requirement for cysteine, the rate-limiting amino acid for glutathione synthesis. Of possible relevance, plasma cysteine levels were severely reduced in over 65% of the autistic children. It is important to note that cysteine is a "conditionally" essential amino acid that is dependent on adequate methionine status; thus, a decrease in methionine precursor levels effectively increases the requirement for preformed cysteine [Griffith, [1999]]. The significant decrease in methionine, cysteine, and glutathione in plasma GSSG observed in the autistic children suggest that precursor availability is insufficient to maintain glutathione levels and redox homeostasis. Consistent with low glutathione levels and increased oxidative stress, autistic children would be expected to have difficulty resisting infection, resolving inflammation, and detoxifying environmental contaminants. Indeed, autistic children have been reported to suffer from recurrent infections [Konstantareas and Homatidis, [1987]], neuroinflammation [Zimmerman et al., [2005]], gastrointestinal inflammation [Horvath and Perman, [2002], Jyonouchi et al., [2005]], and impaired antioxidant and detoxification capacity [Yorbik et al., [2002], Chauhan et al., [2004], Zoroglu et al., [2004]].

The abnormalities in the methionine transmethylation pathway in the autistic children are unusual. Reduced plasma methionine and SAM most often reflect a decrease in MS activity; however, a decrease in MS activity is most often associated with elevated homocysteine levels [Finkelstein, [1988]]. Similarly, an increase SAH is generally a response to an increase in homocysteine due to the reversibility of the SAH enzyme (Fig. 1). Despite a significant decrease in methionine and increase in SAH levels, homocysteine levels were not increased in the autistic children. Although an increase in homocysteine would be anticipated, the modest decrease observed is most consistent with an upregulation of transsulfuration pathway in response to insufficient glutathione synthesis [Mosharov et al., [2000], Banerjee and Zou, [2005]].

One explanation for the simultaneous elevation of SAH and adenosine observed in a subset of the children is a downstream defect in adenosine metabolism. An increase in adenosine is well known to bind to the active site of SAH as a product inhibitor resulting in an increase SAH levels. Consistent with this possibility, previous studies have reported a decrease in adenosine deaminase activity [Stubbs et al., [1982]] and a functional polymorphism in the adenosine deaminase gene in some children with autism [Bottini et al., [2001]]. The increase in SAH and adenosine in a subset of ~20% of autistic children is of clinical concern because SAH is a potent product inhibitor of most cellular methyltransferases. A low SAM/SAH ratio has been associated with impaired methylation capacity for membrane phosphatidylcholine synthesis and DNA methylation in humans [Yi et al., [2000], Iniris et al., [2003]]. The functional consequences of these metabolic abnormalities on membrane dynamics and gene expression would be of considerable clinical interest especially since we have shown that the metabolic imbalance in autistic children is potentially reversible with targeted nutritional intervention [James et al., [2004]]. Studies are underway to determine whether treatment to normalize the metabolic imbalance will ameliorate behavioral symptoms.
Because abnormalities in transmethylation and transsulfuration pathways have been associated with heart disease, cancer, birth defects, and neurologic disorders [Saw, [1999]; Matson and Shea, [2003]; Stover, [2004]; Hobbs et al., [2005]]; aberrations in these pathways have been well-studied and many enzyme-coding loci in these pathways have now been sequenced for common genetic polymorphisms. It is generally accepted that complex diseases are influenced by genetic alterations at multiple and variable loci that interact together to reach a threshold of toxicity that is critical for the expression of the disease [Jones and Szatmari, [2002]]. Epistasis, or the interaction between genes, is increasingly recognized as an important analytic approach to study genetic contribution to complex disease [Cordell, [2002]); Jones and Szatmari, [2002]]. Although epistasis is often used to infer biologic meaning from quantitative data, this approach may be tenuous when complex disease risk is the outcome. However, for gene-gene interactions that are involved in the regulation of a common metabolic pathway for which disease-related alterations have previously been demonstrated, a plausible biologic model can be postulated. In this case, epistasis not only contributes to the understanding of biological mechanisms, it also provides insights into genetic factors associated with disease susceptibility [Selton et al., [2004]].

Based on these considerations, we have initiated a study of candidate genes for proteins that have a functional impact on transmethylation or transsulfuration pathways and oxidative stress. We have used the metabolic endophenotype as a metabolic map for the selection of relevant candidate genes. On an individual level, genotype/metabolic phenotype analysis can provide clues for effective intervention and insights into the basis for individual differences in response to treatment. This is an important future goal that will require a much larger cohort of cases for meaningful correlations.

The reduced folate carrier (RFC) is present on the membrane of every cell and modulates the delivery of reduced folates into the cell [Mathers, [2001]]. The G allele (glutamine > arginine) has been associated with increased risk of birth defects [DeMarco et al., [2003]] and elevated plasma folate as the result of impaired cell uptake [Yates and Lucoc, [2005]]. Relative to controls, autistic children had a significant increase in the frequency of the reduced folate carrier RFC-1 homozygous 80G (33% vs. 26%) and heterozygous 80G (62% vs. 41%). Children with either the RFC-1 GA or GG genotypes were approximately twice more likely to be autistic (OR: 2.28 and 1.96, respectively). Importantly, a significant interaction between heterozygous RFC-1 80GA genotype and the both the MTHFR 677CT and TT genotypes was observed among the autistic children with odds ratios of 3.24 and 4.4, respectively. In addition, an interaction between the homozygous RFC-1 80GG and the MTHFR 677TT genotypes conferred a threefold increase autism susceptibility. Finally, an interaction between 3 and 4 loci was found for the compound heterozygous MTHFR 677CT//1298AC and the RFC 80AG and GG genotypes. The RFC-1 80 G allele is associated with decreased intracellular folate transport and the MTHFR 677 T allele reduces the synthesis of metabolically active folate. Thus, the significant interaction between these MTHFR and RFC genotypes would negatively affect intracellular folate status by two independent mechanisms. Together, common variants in the RFC and MTHFR genes conferred greater susceptibility to autism than either alone and suggest a potent epilogic role for impaired folate-dependent one-carbon metabolism in the susceptibility to autism. Consistent with low intracellular folate availability, methionine levels were decreased among most autistic children. Thus, the metabolic and genetic data support the possibility that the observed alterations in methionine metabolism may be due, in part, to a genetic predisposition for a functional folate deficiency.

TCN2 is the major transport protein required for the cellular uptake of vitamin B12 by receptor-mediated endocytosis [Seetharam, [1999]]. Previous studies indicate that a common 776G > T transition in the TCN2 gene (proline > arginine) decreases the binding affinity of TCN2 for vitamin B12 and reduces the transport of B12 into cells [Afram et al., [2001]; Miller et al., [2002]]. Vitamin B12 is an essential cofactor for the MS reaction and accepts the methyl group from 5-methylfolate to generate methionine from homocysteine in the initial step of the methionine transmethylation pathway (Fig. 1). The frequency of the homozygous TCN2 776GG variant was significantly increased among the autistic children compared to controls (26% vs. 16%) and the GG variant was associated with a 1.7-fold increased risk of autism. In contrast, the combined wild-type and heterozygous TCN2 genotypes (CC + CG) had an odds ratio of 0.55. Of particular relevance to neurologic disorders, the TCN2 776GG variant has been associated with lower levels of transcobalamin-bound B12 (holotranscobalamin II) in the cerebral spinal fluid of Alzheimer's patients [Zetterberg et al., [2003]]. B12 deficiency is well known to have neuropsychiatric consequences in adults [Zucker et al., [1981]] and adversely affect neurodevelopment during infancy [Graham et al., [1992]]. In toddlers, severe B12 deficiency has been associated with developmental regression similar to that observed in ~33% of autistic children [Grattan-Smith et al., [1997]]. It is provocative to note that the TCN2 GG variant would be expected to negatively affect B12 cofactor availability for the MS reaction just as the interaction between RFC-1 80 G and MTHFR 677 T alleles would be expected to reduce methylfolate availability for the same MS reaction. Although speculative, the low methionine levels found in many autistic children support the possible contribution of all three variant alleles, independently or combined, to impaired methionine synthesis. In addition, children with a genetic predisposition to impaired methionine synthesis would be especially vulnerable to further reduction in enzyme activity with exposure to endogenous or exogenous oxidative stress [Meszarov et al., [2000]].

The third genetic variant found to be significantly more frequent among autistic children was the COMT 472 G allele. The methylation of dopamine by COMT is an important mechanism for dopamine inactivation and dopaminergic tone in the CNS [Nisoulion, [2002]]. The G > A transition at position 472 (valine > methionine) has been shown to influence protein expression and enzyme activity in an allelic dose/response manner [Chen et al., [2004]]. The val allele is associated with thermostability and high activity whereas the met allele is associated with low activity and thermostability [Chen et al., [2004]]. Compared with met carriers, individuals homozygous for the val allele showed poorer attentional control and performance on tests of executive cognition associated with inefficient prefrontal activity [Bisio et al., [2003]]. In other studies, the met allele, which encodes the low activity variant, was associated with better performance on tests of prefrontally mediated cognition [Egan et al., [2001]; Diamond et al., [2004]]. The high activity homozygous GG (valval)
genotype was present in 29% of autistic cases and 20% of unaffected controls and was associated with a 1.74-fold increased susceptibility to autism. Unexpectedly, we found an apparent synergistic interaction between homozygous TCN2 GG and homozygous COMT GG genotypes (four mutant alleles) that increased autism risk sevenfold. Both the TCN2 and COMT allelic variants would be expected to decrease CNS methionine and SAM levels by reducing availability and increasing consumption, respectively. A direct biochemical interaction between dopamine and vitamin B12 deficiencies is not known; however, independent deficiencies in both are well known to negatively affect neurologic function.

Marginal increases in variant allele frequency with borderline significance were found for the GST M1 null genotype (OR: 1.37; CI: 0.98, 1.96) and the combined MTHFR CT + TT genotypes (OR: 1.38; CI: 0.96, 1.98). Despite a modest independent effect, the MTHFR 677 T allele showed significant interactions with the RFC-1 G allele as described above. Similarly, the GST M1 null genotype achieved marginal significance in the univariate analysis, but showed a highly significant interaction with RFC-1 G allele. Children with combined RFC-1 heterozygous 80GA and GST M1 null genotypes had a 3.78-fold increased susceptibility to autism and children with both the RFC homozygous GG and GST M1 null genotypes had a 2.67-fold increase in risk. In contrast, a decrease in MTRR homozygous GG genotype among autistic children was suggestive of a protective effect (OR: 0.61). This observation could be interpreted as the A allele representing the risk factor as was concluded for risk of neural tube defects [Rettion et al., 2004].

Given the relatively small number of cases and controls in the present study, it is encouraging to note that several susceptibility alleles that perturb a common metabolic pathway were increased among the autistic children. This supports the possibility that some forms of autism could be a manifestation of a genetic predisposition to abnormal methionine/glutathione metabolism and oxidative stress. Further, the abnormal metabolic profile observed in a significant proportion of autistic children suggests the provocative possibility that some autistic behaviors could be a neurologic manifestation of a genetically based systemic metabolic derangement. Such a paradigm shift from a neurodevelopmental disorder to a broader systemic disorder would widen the biologic basis of autism to encompass not only the neurologic manifestations but also the gastrointestinal and immunologic pathology that have received increasing attention in recent years [Horvath and Perman, 2002; Jyonouchi et al., 2005]. Supporting this possibility, abnormalities in folate-dependent methionine and glutathione metabolism have been associated with gastrointestinal and immunologic dysfunction in addition to impaired CNS function [Martensson et al., 1990; Bains and Shaw, 1997; Droge and Breitkreutz, 2000]. The hypothesis that a genetic component of autism could involve multiple susceptibility alleles that interact to create a fragile, environmentally sensitive metabolic imbalance is worthy of further pursuit. Moreover, if some children with autism are confirmed to have an abnormal metabolic profile, treatment for this form of autism can be directed toward correcting the metabolic derangements and potentially ameliorating the autistic symptoms.

In summary, we have discovered two key metabolic abnormalities among many autistic children that are indications of significant impairment in methylation capacity (↓SAM/SAH) and in antioxidant capacity and redox homeostasis (↓GSH/GSSG). The significant increase in plasma GSSG levels indicates that these children are under oxidative stress. Preliminary genetic analysis indicates several polymorphic variants affecting methionine and glutathione metabolism are significantly increased among the autistic children supporting the possibility that the metabolic imbalance may be genetically influenced. Clearly, these new findings should be considered preliminary until confirmed in larger population-based studies.

Acknowledgements

The authors gratefully acknowledge and thank all of the autistic children and their families who made this study possible. We thank Laurette Janak (Buffalo, NY) for her help with planning and study logistics.
